## *An agent-based model for the exploration of mountain grassland community dynamics*

Clément Viguié

November 9, 2017

This document is a detailed description of the *MountGrass* model. This description is based on the ODD protocol of Grimm et al.. The model is inspired by multiple other forest and grassland models (for grassland models see particularly Taubert and Lohier). It differentiates itself from these models by the incorporation of phenotypic plasticity in a generalizing framework for plant functioning. This allows it to be used to both to explore the fundamental effects of phenotypic plasticity the dynamics of rich grass communities and the impact of the phenotypic plasticity on plant interactions. The general approach and the practical details are further detailed in this document.

### *Model overview*

#### *Model purpose*

The development of *MountGrass* is motivated by the need for a flexible tool to explore the complex dynamics of mountain grassland communities, in the context of global change. This tool should, by a better understanding of community dynamics and representation of plant strategies and interaction, also help in the assessment of ecosystem services in new conditions. We believe that to capture the dynamic of such communities, we need to understand and represent first the individual response of plants to fluctuating levels of resources, and the impact of plants on the resources. Individual responses and relative impact should follow general rules of plant physiology but also integrates specific behaviour based on the species resource use strategy and individual characteristics. Therefore the model should allow to follow distinct individuals from different groups (e.g. species) in a spatially explicit environment where they compete for resources.

Moreover, since we focus on the community levels, coexistence mechanisms are important and we should include a certain number of these if we want to maintain diversity to observed levels. These mechanisms include: multiple resources competition (water and light), spatial and temporal heterogeneity of resource levels, strategic trade-off between species, perturbation mechanisms (frost, management), link to meta-population, etc...

The model is built to try to satisfy conditions to reproduce and explore mountain grassland community dynamics. In the current version of the model (*MountGrass2.0*), a generalist approach has been privileged, and focus on some coexistence maintenance mechanisms and integration of phenotypic plasticity framework. In this state the model has to be seen as a toy model with good generalisation potential. The link between to ecosystem services are not included, but we can easily imagine to compute them from the community trait distribution. All processes and mechanism are detailed below.

### State variables

In mountain grasslands individuals (tillers) generally do not grow big and interact only with close neighbours and form little patches. And thus it is possible to represent rich community at a fairly small scale ( $\approx$  dm or m), but the spatial resolution should be relatively fine ( $\approx$  cm) to capture inter-individual interactions. Because the model is intended to explore climate change impact on mountain grasslands, it can runs on multiple growth seasons separated by snow covered periods, but must also integrates the intra-seasonal variations at daily scale. Mountain weather (mostly temperature) is known for its large hourly variations, it would however require too much computational power to consider such variations. In addition to this argument, we believe that even-though they imply physiological flexibility and specific strategies for plants experiencing these conditions, they will not have a huge impact on overall community dynamics changes caused by the climate change. That why hourly variations will not be considered, and physiological processes are estimated at the daily time scale.

Scales

The plants are described in the model by state variables described in table 3. The best way to understand how plant are represented is to imagine two homogeneous cylinders on top of each others, the shoot cylinder varying in radius and height representing the light acquisition (and shading) zone, and the root cylinder varying only in diameter (because of shallow soil in mountain ecosystems) representing the water acquisition zone. These cylinders are centered on cells of the torus simulation plan.

Plants

In addition to classic variables (age, position, height, diameter, shoot and root biomasses) the plants are described by traits, that can be species specific or non-specific, others are variable (SLA, SRL) and depend on particular traits that are unique to this model: the **ratio between active tissue and structural tissue** (in shoot and root) (variables  $\frac{act}{str ag}$  and  $\frac{act}{str bg}$  in table 3). This couple of traits come from the evidences that numerous trade-of observed in leaves can be explained (at least partially) by this allocation trade-of between active tissue producing organic matter, but increasing respiration, and structural tissue that increase tissue lifespan.

Plants are characterised by state variables that describe them individually, but they also share common characteristics with individuals of the same group, (we will refer as *species* to talk about this group in the rest of the document even-though it could be a group at an other scale (i.e. population, clones). These species are the groups present in the meta-population and that can invade the simulated ecosystem. There are described by multiple traits characterising the strategy of the species (table 2).

Species

The seed-bank is the transition state between the different seasons. Individuals may persist thanks to stored resources, but they can also reproduce by the production of new individuals. Lot of grasses use clonal reproduction, in addition or replacement of sexual reproduc-

Seed-bank

Variable	Description	Unit
x	x position on the grid	cells
y	y position on the grid	cells
age	age	days
sp	species	-
$BM_{ag}$	above-ground biomass	g
$BM_{ag, sen}$	senescent above-ground biomass	g
$SLA_{sen}$	senescent above-ground biomass	$cm^2 \cdot g^{-1}$
$BM_{bg}$	below-ground biomass	g
stem	stem biomass	g
$\frac{act}{str}_{ag}$	above-ground active on structural biomass ratio	g/g
$\frac{act}{str}_{bg}$	below-ground active on structural biomass ratio	g/g
h	height	cm
r	shoot radius	cm
r_r	root radius	cm
$light_{exp}$	above-ground potential resource availability	gH <sub>2</sub> O.leaf area
$water_{exp}$	below-ground potential resource availability	gH <sub>2</sub> O.root area

Table 1: State variables of individual plants

Trait	Range (close range)	unit	trade-of or strategy
seed mass	(0.00001 - 0.001)	g	seed output vs seedling productivity
maturity	-	green biomass	flowering time vs reproduction potential
fract_dev	0-1 (0.05-0.6)	-	blooming vs persistence
fract_rep	0-1 (0-1)	-	reproduction vs persistence
geometric constant ( $k_g$ )	(0.1 - 20)	-	competition sensitivity vs self-shading
plasticity stability	0-1 (0.8-1)	-	genetic information vs experience
initial water resource	(0.001 - 0.05)	$gH_2O \cdot cm^{-2}$	water resource niche
initial light resource	(0.001 - 0.05)	$gH_2O \cdot cm^{-2}$	light (in $H_2$ equivalent) resource niche
$\frac{act}{str}_{ag,d}$	(0.03 - 0.3)	$g \cdot g^{-1}$	active vs structural tissue
$\frac{act}{str}_{gg,d}$	(0.03 - 0.3)	$g \cdot g^{-1}$	active vs structural tissue
mean temp.	(0 - 5)	°C	early vs late germination
germination rate	0-1 (0.5 - 1)	-	good season bet-hedging
thickness	(0.012 - 0.05)	cm	WUE vs light efficiency (not in this version)

Table 2: Species traits

tion. This type of reproduction is characterised by a persistent link between the newly produced individuals and the parent one that allow the two to communicate and exchange resources. Such dynamics are complex and costly to represent as the link between ramets must be stored and strategies defined for the resource distribution (see Oborny 2012) for more details on clonal growth modelling). To avoid too much complexity, it is possible to approximate the representation of clones to big seeds with little dispersion around the parent plant<sup>1</sup>. For this reason, reproduction mechanism is reduce to sexual reproduction mechanism with production of "seeds". Seeds are stored in the seed-bank and only defined by their species and positions.

<sup>1</sup> This would take advantage of dispersion kernels. Not implemented in current version. Dispersion is uniformly random within the simulation plan

Soil is an important aspect of the model as it drives (with the precipitations) the water competition between individuals. It is however limited, as in numerous vegetation models, to a grid characterised by: its capacity to retain water, and its depth. Only the first component (water retention capacity) is spatially variable and is described by the critical water content (minimum soil water content), the saturation water content (maximum water content, the water non absorbed leaves the system we assume the same root depth for all species), and the current water content (temporally variable, depending on competition, precipitation and evaporation, between the critical and the saturation water content) only dynamic variable among the three.

Soil

### *Process overview and scheduling*

As mentioned the model runs at daily step to capture individual responses to conditions and over multiple seasons to capture long temporal dynamics. Some processes occur (or are evaluated) at the daily time-step, some at the season time-step. The following ordered list presents the different processes and the scheduling over days and season of one simulation.

One season can be divided in the following parts:

- *germination*: marks the beginning of the season when the ground is no more snow-covered;
- *growing season*: consists in daily processes like competition, production of organic matter (OM), allocation, and death lottery;
- *reproduction-invasion-persistence*: marks the end of the season when the first persistent snow-fall occurs. OM invested in reproductive tissues turns into seeds that are sampled to create the seed-bank. Seeds from the meta-population may integrate the seed-bank. Persistent perennial lose most of their biomass but storage (and eventually stem) and regrow from stored organic mass at the beginning of the following season.

The *growing season* part consists in all processes evaluated every day of the growing season. These processes are:

- *light competition*: the individual potential photosynthetic activity is computed based on average daily light and shoot properties;
- *water competition*: evaporation and the individual water update (and potential water uptake) are computed based on potential transpiration, water availability and potential evaporation;
- *production*: respiration and production are computed to give the net productivity in OM;
- *senescence*: based on lifespan a part of tissue is no longer active.
- *death*: death of individuals based on their age and their desiccation stage (number of consecutive days with negative growth).
- *allocation*: allocation of produced OM to the different carbon pools of the plant.
- *grazing/cutting*: (optional) grazing or cutting of plants to a certain height. The grazing can be selective.<sup>1</sup>

<sup>1</sup> remarks in grey are features or components implemented in the model but not used and-or calibrated.

## Design concepts

### Design concepts

This part clarifies the rules that drives the dynamics of the model.

The purpose of the model being to understand the rules that drive the community responses, we tried make the community dynamics emerge from the underlying processes of plant growth, resource use and reproduction. That means that population dynamics is at least partially emergent from the surviving and reproducing individuals. 'Partially emergent' because it depends on the invasion rules applied to the system. The traits and biomass distribution that describe the community are completely emergent from the individual traits exposed by the individuals and their relative biomass and abundance.

Emergence

Plants have in theory many options to adjust their phenotype and increase their fitness in response to changes in environmental conditions (resource availability, temperature, ...). High diversity of mountain grasslands suggests that multiple strategies coexist and that individuals do not change to converge toward a unique strategy. These strategies are set up at the species level by the species specific traits (see table 2). Therefore, individuals may only adapt morphological traits but not strategic traits (unless there is an epigenetic mechanism added). These morphological traits are: the relative biomass of shoot and root, relative proportion of active and structural tissues in each leaves, and roots (controlling respectively the SLA and SRL and the overall resource acquisition cost)<sup>2</sup>. Geometry traits (distribution of leaves and roots within space) are not considered plastic as grasses have far less control on their geometry than forbs or trees. Root distribution plasticity has been shown to greatly improve the individual and community productivity (Gemini aticle), but to keep the model (and implementation) simple we will ignore root distribution plasticity and foraging strategies to focus on allocation problems instead of

Adaptation

<sup>2</sup> and optionally the proportion of stored OM dedicated to frost resistance and not to growth

spatial distribution questions. Shallow soils and relative small rooting zone are also arguments to ignore spatial distribution plasticity for roots.

In the model the realised fitness can be estimated as the capacity of plants to maintain themselves or their descendants through time. It emerges from the productivity, allocation to storage or reproductive carbon pools, and survival. Assessing fitness as the average number of persistent individuals is however a bit hazardous in simulations limited in time and to a relatively small spatial scale. Plus, plants cannot easily make prediction of such variable to adjust their phenotype. They need a proxy function for fitness that integrate measures of external conditions to evaluate the best strategy to develop. As said above, this strategy should be a composite between the species strategy and individual adjustment specific to the individual experience of the environment. Plant fitness is estimated by individual plant thanks to a gain function integrating current phenotype, species strategy and projection of future conditions. This gain function can take multiple forms and be more or less constraint. In the context of the model, the function should include a measure of productivity that relies on the principle of functional equilibrium - that is the allocation of organic matter to maintain the balance between the shoot activity (transpiration) and root activity (water uptake). This equilibrium can be achieved by changes in shoot:root ratio only, or also changes in active over structural tissues ratio. Further details about the gain function are discussed in the dedicated paragraphs (). More complex form of functional equilibrium incorporating nutrients (like nitrogen) could be added to the framework of this model.

Fitness

Adaptation or plasticity mechanisms imply that agents have an insight of what will be the future. In *MountGrass* we consider that plants have two main sources of information. The first source of information is the genetic information. Indeed, the evolutionary process of genotype selection has led to the selection of genotypes adapted to the local conditions. This selection relationship can be seen as a link between environmental conditions and genetic information. Because plants cannot fully predict future environmental conditions, they grow following (at least partially) the plan contained in genetic information that match conditions where previous generations grew in. This is an internal *a priori* information about the external conditions. If the conditions where the seed grow change from the conditions its genotype has been selected for, the genetic information does not fit the environmental conditions is not sufficient enough to build a working phenotype. In this case, if the plant has a plasticity capacity, it can integrate the second source of information, in the form of the experienced conditions, to its "a priori" and forge a new estimation of what conditions will be. One question emerges to this idea is: how to create an image of future conditions and how to balance the genetic *a priori* information with the experienced infor-

Prediction

mation ? This balance can be described by a term of "reactivity" that describe the relative weight of genetic and experienced information. A reactive species will give a higher weight to experienced condition information, whereas an stable species will give a higher weight to genetic information.

The way the two source of information are brought together and used to define the plant phenotype is at the core of plant strategy and is the main feature of the model *MountGrass* .

### *Details*

Further details on daily mechanisms are described in the following paragraphs.

### *Initialisation*

The model doesn't need particular initialisation if the state of the community species pool, the seedbank and the soil are given as inputs. Otherwise, a set of  $E(n/s)$  individuals are created from a set of  $s$  species (randomly generated if not given) and randomly positioned on the soil grid, where  $s$  and  $n$  are respectively the number of species and the approximate number of individuals within the grid. Soil grid is also randomly generated within default ranges for critical and saturation water contents then slightly smooth, and homogeneously filled ( $filling = \frac{w_{cont} - w_{crit}}{w_{sat} - w_{crit}}$ ).

### *Inputs*

*MountGrass* needs system state information (individuals, species, seed-bank and soil) and climate data. If the state of the system is not completely given, then the complete state is generated in the initialisation. The daily climate data at must contain the following fields:

- *date*;
- *radiance*, in  $Watt.m^2$ ;
- *precipitation*, in mm;
- *mean temperature*, in K;
- *mean day temperature*, in K;
- *min temperature*, in K;
- *max temperature*, in K;
- *relative humidity* in %;

Vapour pressure deficit is then computed from temperature and relative humidity.

The climate data must explicitly differentiate the seasons (delimited by the first day of the year without snow and by the first day of the second semester with snow).

### Submodels

Individuals from the seed-bank randomly germinate according to their species specific germination rate. Germination consist of investing a percentage (*mob* parameter) of the seed mass into shoot and root biomass according to default traits. This is coupled with a round of random seed death following uniform law of parameter *seed<sub>surv</sub>*. Living non germinating seeds stay in the seed-bank until the next season.

#### Daily processes

Light competition is central in all vegetation model as it constraints the photosynthetic activity and so plant growth. To avoid costly calculation of ray propagation we assume vertical homogeneous top radiation. Relief and orientation effects is taken into account in the computation of irradiance data.

Light competition sub-model allows calculation of individual potential photosynthesis activity and light at soil surface for evaporation calculation.

Competition for light is calculated independently for each pixel, potential photosynthetic activity is then aggregated at the individual level. Each pixel can be seen as a column of homogeneous layers containing at least one individual (top layer). For each layer the light transmission is computed based on leaf density.

$$I(h) = I_0 e^{-LAI(h)} \quad (1)$$

where  $LAI(h)$  is the cumulative LAI at the bottom of layer  $l$  (between  $h$  and  $h + \Delta_h$ ) defined as the homogeneous layer delimited by the top of consecutive individuals in the same pixel. The LAI is calculated like this:

$$LAI(h) = LAI(h + \Delta_h) + \Delta_h \cdot pix\_width^2 \sum_{i \text{ in } l} d_i \cdot coverage_{i,p} \quad (2)$$

where  $d_i$  is the individual leaf area density corrected by the coverage ( $0 < coverage \leq 1$ ) of the pixel  $p$  by the plant  $i$ ,  $\Delta_h = (h_l - h_{l-1})$  is the height of the layer  $l$ .

Following Thornley and Johnson, the potential photosynthetic leaf activity is calculated as:

$$P_{leaf}(h) = \frac{\alpha \cdot I_{leaf}(h) \cdot P_{max}}{\alpha I_{leaf}(h) + P_{max}} \quad (3)$$

where  $I_{leaf}(h)$  is the light absorbed by the leaf at height  $h$ ,  $\alpha$  the initial slope of the light response curve and  $P_{mi}$  the maximum photosynthetic rate per unit of area and unit of time.  $I_{leaf}$  is the radiance at the leaf surface, derived by correcting the radiance at the top of the layer following the equation used in Taubert with the extinction and transmission coefficients  $k$  and  $m$ :

$$I_{leaf}(h) = \frac{k}{1 - m} I(h) \quad (4)$$

### Germination

### Light competition

Figure 1: Net gain function and its first derivative.

Looks like there is some kind of mismatch here.

Figure 2: Photosynthetic saturation function

The equation (3) can be integrated over the leaf surface by mixing it with equations (1) and (2) to give the total potential photosynthesis for layer  $l$  in pixel  $p$ :

$$P_{leaf}(p, l) = d_i.coverage_{i,p} \cdot \Delta_h(l) \int_{h_{bottom}}^{h_{top}} P_{leaf}(h) \quad (5)$$

the total leaf potential photosynthesis is then calculated as follow:

$$PS_{pot} = \sum_{p \text{ in shoot } l} \sum_{l \text{ in pixel}} P_{leaf}(p, l) \quad (6)$$

Potential photosynthesis must then be converted to potential transpiration to define the water demand. The conversion from photosynthesis to transpiration is done by dividing the potential photosynthesis by the water use efficiency ( $WUE$ ). The potential activity of leaves are also dependent on the regulation of stomata so the transpiration can be written:

$$transp = \frac{PS_{pot} \cdot g_{red}}{WUE} \quad (7)$$

Photosynthesis depends on gasses exchanges at the leaf surface. These fluxes result from relative concentration in carbon dioxide and water, and from the stomatal conductance. Stomatal conductance is reduced and limits productivity when vapour pressure deficit is too high <sup>1</sup>. A linear relationship describe this relationship:

$$g_{red} = 1 + VPD_{g\_red} \quad (8)$$

Stomatal regulation

<sup>1</sup>  $g_{red}$  is set to 1 for current version to avoid potential problems between allocation and regulation

Potential evaporation is calculated for each pixel depending on the light at soil surface:

$$\beta = 0.25 * (1 - \cos(\frac{\theta}{\theta_{sat}} * \pi))^2 \quad \text{if } water_{cont} \leq water_{sat} \quad (9)$$

$$\beta = 1 \quad \text{otherwise} \quad (10)$$

$$PET = 0.0023 \cdot \sqrt{(T_{max} - T_{min})} * (T_{mean} + 17.8) \quad (11)$$

$$evap = PET \cdot \beta \cdot I_{surface} \cdot daylength \quad (12)$$

Evaporation

Figure 3: Evaporation limitation function.

Water competition is also computed at the pixel level. To determine the water uptake, first the individual water demand is computed as the minimum between the transpiration and the potential water uptake. Transpiration demand per pixel is easily calculated by dividing the total potential transpiration by the volume in the pixel  $V_{i,p}$  over the overall root volume  $V_i$ . Water potential uptake is the product of root area in the pixel and root water uptake rate reduced by the water availability reduction factor  $U_{lim}$ , leading to the water demand

Water competition

for individual  $i$  in pixel  $p$ :

$$transp_i(p) = transp \cdot \frac{V_{i,p}}{V_i} \quad (13)$$

$$Wpot_i(p) = Root_{area}(p) \cdot U_{max} \cdot U_{lim} \quad (14)$$

$$Wdem_i(p) = \min(transp_i(p), Wpot_i(p)) \quad (15)$$

$$(16)$$

where, the limitation function  $U_{lim}$  is defined as in <sup>1</sup>:

$$U_{lim} = \exp\left(\beta_\theta \left(\frac{1}{\theta_s - \theta_{crit}} - \frac{1}{\theta - \theta_{crit}}\right)\right) \quad \text{if } \theta < \theta_{crit} \quad (17)$$

$$= 0 \quad \text{otherwise} \quad (18)$$

The total water demand per pixel is then the sum of all individual water demand of the pixel and potential evaporation. If the total water demand exceeds the total water availability ( $W_{av}$  product of water content and soil volume in the pixel) then the available water is distributed proportionally to the individual demand.

$$Wup_i = Wdem_i \cdot \frac{Wdem_{total}}{\min(Wdem_{total}, W_{av})} \quad (19)$$

The potential water uptake ( $Wpup$ ), non limited by the transpiration is calculated the same way but considering  $Wdem_i = Wpot_i$  in equation (19).

Because the water competition is computed at the pixel level, there is no compensation between two pixels containing respectively not enough and too much water.

No radial flow of water between pixel is implemented in the model. This simplification leads inevitably to edge effects, but allows simpler implementation and is partially covered by the effect of the pixel size. Indeed, increasing pixel size would have similar effect in the pixels at the border of the rooting zone than radial flow because it would increase the potential water pool plant has access to.

Once potential and realised transpiration and water uptake are computed, plant productivity can be calculated.

Following previous vegetation models, the respiration is decomposed in growth respiration and maintenance respiration. The first is function of trait values, biomass and temperature:

$$R_m = \left(R_{act} \cdot (Act_{ag} + Act_{bg})\right) \cdot daylength \cdot T_{effect} \quad (20)$$

where  $R_{act}$  is the respiration rate of active tissues, and  $Act_{ag}$  and  $Act_{bg}$  are the active biomass pools in shoot and root.

Net Primary production (in  $CO_2$  equivalent) can then be calculated the difference of GPP and respiration, then converted in OM production thanks to tissue carbon content (under the assumption of fixed carbon content for leaf and roots between species):

$$NPP_{carbon} = (1 - R_g) \cdot (WUE \cdot \min(w_{up}, transp) - R_m) \quad (21)$$

$$NPP_{OM} = NPP_{carbon} \cdot (12/44) / TCC \quad (22)$$

Figure 4: Water uptake limitation response function to soil saturation

Production, and respiration

Here  $R_g$  is a fixed parameter but is set to 0 if the difference between gross productivity ( $GPP = WUE.min(w_{up}, trans_p) - R_m$ ) and maintenance respiration is negative.

Temperature has a effect of plant activity, this effect can be modelled by a bell shape function around an optimum value of 20 °C. See Lohier for details.

Temperature effect

The projection of environmental conditions is central in any implementation of phenotype plasticity. Differences between the current perception of environment and the projections lead to adjustment of phenotype to increase fitness. In the model *MountGrass* this projection results from the averaging of two key concepts: memory and perception. The latter is relatively simple to understand and corresponds to the perceived resource availability computed as the mean potential exchange rate per unit of area (total leaf or root area) and per hour<sup>1</sup>:

Condition estimation

$$light_{exp} = \frac{transp}{exchangearea_{ag}} \quad (23)$$

$$water_{exp} = \frac{Wpup}{exchangearea_{bg}} \quad (24)$$

<sup>1</sup> the hourly measure is used instead of daily measure to simulate the ability of plant to perceive the photoperiod. This is an easy way of taking into account one aspect of seasonality without complexifying the model.

(25)

The former is related to the species (or group) history and result from processes of selection and acclimatation. It is the default projection of resource availability when the plant is not plastic.

$$light_{est} = (1 - \tau).light_{exp} + \tau.light_{est}.daylength \quad (26)$$

$$water_{est} = (1 - \tau).water_{exp} + \tau.water_{est}.daylength \quad (27)$$

Because these are supposed to be expected conditions for the future, other formulation can be used instead of an average that is likely to introduce a lag in estimations.

Allocation is primordial in plant development and we must be careful when modelling it. We can distinguish two phases in plant development that impact a lot OM allocation: the vegetative phase, and the reproductive phases. The separation between these phases and the development allocation are discussed in the following paragraphs.

Allocation

**Maturity:** Plants are considered mature in *MountGrass* when the phenologic variable has reach a species specific threshold. The phenologic variable can be either the age, the height, the biomass, degree.days, in the current version age is used.

**Allocation to stem:** Even-though grasses do not grow high vegetative parts like trees, some grow vertically and they are exposed to stronger winds than most of forest, and therefore need structural supports. Not all grasses grow stem, so we suppose that the supporting function is fulfilled by the leaf structural tissue. The minimal mechanical support needed is calculated as a function of above-ground

biomass:

$$support = \alpha_L \cdot (BM_{ag})_L^{\gamma_L} \quad (28)$$

where  $\alpha_L$  and  $\gamma_L$  are the shoot allometry and shoot allometry exponent.

To avoid complex allocation optimisation problem, the allocation of supporting tissue is done before any other allocation. If the support is not sufficient, no organic matter can be invested in vegetative development. The biomass the plant needs to invest in the stem is defined as:

$$\Delta_{stem} = \max(support - (stem + Str_{ag}), 0) \quad (29)$$

where  $Str_{ag}$  is the structural biomass in shoot.

Allocation of produced organic matter is central in vegetation as it shapes the plant and define the strength of the different organs. There are multiple ways to model the distribution of produced organic matter between the plant organs. We believe that such mechanism has great impact on individual development and response to external conditions, and so on community dynamics. To explore the role of this mechanism, multiple options are implemented. The different allocation algorithms are summarised in the following table:

Algorithm	Objective	variable RSR	variable SLA-SRL	stochastic
Fixed	—	○	○	○
Equilibrium	functional eq.	●	●	●
Eq-F	functional eq.	●	○	●
Optimisation	instantaneous gain	●	●	●
Optim-F	instantaneous gain	●	○	●

Table 3: Allocation algorithms implemented in *MountGrass*

**Fixed trait allocation:** The fixed allocation supposes the allocation on OM to maintain trait values to fixed species specific values. The shoot:root ratio may however change to maintain functional equilibrium. The shoot root ratio is derived from the following equation of the functional equilibrium:

$$SLA \cdot BM_{ag} \cdot light_{est} = SRL \cdot BM_{bg} \cdot water_{est} \quad (30)$$

$$\frac{BM_{ab}}{BM_{bg}} = \frac{SRL \cdot water_{est}}{SLA \cdot light_{est}} \quad (31)$$

where  $light_{est}$  and  $water_{est}$  are the estimated resource availabilities.

**Pseudo-optimization:** Another approach to allocation is to try to optimize it based on a fitness proxy. This proxy can be the sum of NPP, tissue turn-over loss and plasticity cost. The individual performance is calculated as:

$$Perf = NPP_f + TO_f + Stem_f + survival_f \quad (32)$$

where  $NNP_f$  is the projected NPP based on the estimated activity of shoot and root, and estimated temperature,  $TO_f$  is the biomass lost due to turn-over,  $Stem_f$  is the biomass needed in the stem and

that will not be invested is the active tissues and  $survival_f$  is the total biomass multiplied by the estimated survival chances.

Having a performance function is not sufficient to find the best allocation scheme, and a research algorithm must be used. To avoid the very costly use of R internal optimisation function, a pseudo gradient approach is used. This approach estimates the performance of allocation to the four carbon pools (active tissue in shoot, structural tissue in shoot, active tissue in root and structural tissue in root) for 5 allocation schemes: full allocation to one of the pools and balanced allocation to all pools. Then investment in the different pools is calculated as the sum of relative performances multiply by allocation schemes. This algorithm is however weak and must be redesigned.

**Plastic trait equilibrium:** Another approach can be easily derived from the previous one and extend the principle of the first: the functional equilibrium with plastic traits. This approach consists in using the same algorithm as pseudo-optimisation mechanism but measure performance with a function negatively related to the difference between estimated shoot and root activity. Such mechanism would nonetheless require the algorithm to look for close solutions within the allocation space to avoid convergence or drift from species strategy.

**Trait update:** Plasticity in trait suggests that trait values are modified in time. Because plants are described by single values (e.g. one SLA value for all leaves), this values must be updated after the plastic allocation. This values could be updated as average of old tissue value weighted by old biomass and new tissue value weighted by the freshly produced biomass. This however would work only if active on structural tissues ratio were linearly link to others traits. This is not the case, it is then simpler to consider that organs have uniform active and structural distribution. This hypothesis suggests that whenever the allocation scheme change, old tissue reallocate their own biomass to follow the new scheme. Nevertheless, to avoid full plasticity allowed by this hypothesis, the changes in trait carbon pool sizes is limited by the produced biomass available for plant development.

From this, supposing homogeneous distribution of active and structural tissues within an organ allow to directly link the size of the carbon pools to average traits by the following relationships:

$$th_a = \frac{\frac{act}{str_s} \cdot th \cdot \rho_{ss}}{\rho_{as} + \frac{act}{str_s} \cdot \rho_{ss}} \quad (33)$$

$$SLA = \frac{1}{(th_a \cdot \rho_{as} + (th - th_a) \cdot \rho_{ss}) \cdot V_t} \quad (34)$$

$$s_a = \frac{\frac{act}{str_r} \cdot s_{root} \cdot \rho_{sr}}{\rho_{ar} + \frac{act}{str_r} \cdot \rho_{sr}} \quad (35)$$

$$SRL = \frac{1}{(s_a \cdot \rho_{ar} + (s_{root} - s_a) \cdot \rho_{sr})} \quad (36)$$

Senescence is the process of aging of tissues. This process usually occurs at the scale of an individual organ (e.g. a leaf), however **MountGrass** does not consider organs independently because it would be complex and computationally expensive to follow multiple leaves and roots for all individuals. So the process is considered homogeneous over all tissues. To emulate the senescence process senescence is calculated from the tissues lifespan, giving :

$$sen_{leaf} = \frac{1}{LLS} \quad (37)$$

$$sen_{root} = \frac{1}{RLS} \quad (38)$$

Because **MountGrass** does not contain any mechanism preventing plant from growing only active tissues<sup>1</sup>, it is necessary for this cost function to make this strategy unreliable. This is then expressed as follow:

$$LLS = LLS_0 * (1 - p_{actroot}^{LSs_1}) \quad (39)$$

$$RLS = RLS_0 * (1 - p_{actroot}^{LSr_1}) \quad (40)$$

where  $LLS$  and  $RLS$  are respectively the leaf and the root lifespans calculated as negative log-linear relationships with proportion of active tissue.

Root senescent tissues disappear from the system. Information about senescent aboveground biomass is stored, but senescent biomass effect of light competition is ignored in this version because as it is implemented senescent tissues appear early in plant development and have large negative effect on light absorption.

To the natural senescence and artificial cost of having only active tissue, an additional component can be added to the turn-over rate: the negative NPP. In case of negative NPP the biomass will be taken from the already allocated following the shoot root ratio. This can lead to a lower overall productivity (negative growth during unproductive periods) but also changes in the equilibrium if tissue have different efficiencies.

Death is modelled as in Reineking 2006. Age and desiccation (negative NPP) are the two reasons why a plant can die. The two death mechanisms are simulated by independent random loteries following the following survival probabilities:

$$P_d = \exp \left( - \left[ \left( \frac{des}{\alpha_d} \right)^{\gamma_d} - \left( \frac{\max(des - 1, 0)}{\alpha_d} \right)^{\gamma_d} \right] \right) \quad \text{if } NPP \leq 0 \quad (41)$$

$$= 1 \quad \text{otherwise} \quad (42)$$

$$P_a = \exp \left( - \left[ \left( \frac{age + 1}{\alpha_a} \right)^{\gamma_a} - \left( \frac{age}{\alpha_a} \right)^{\gamma_a} \right] \right) \quad (43)$$

$$(44)$$

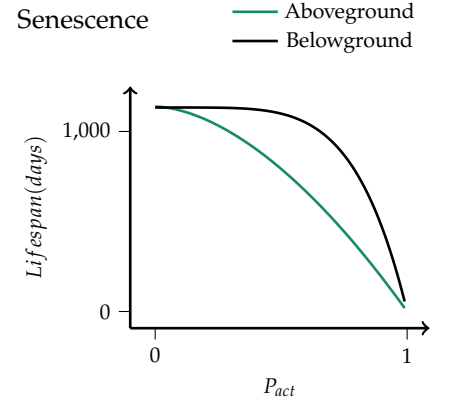

Figure 5: Water uptake limitation response function to soil saturation

<sup>1</sup> it was intended to make the WUE negatively correlated to the amount of structural tissue per area.

Figure 6: Age related survival probability function

State of dead individuals is store until the end of the season when seed are stored in the seed bank. Seeds of dead individual then join other seeds.

**Sexual & clonal reproduction:** reproduction is handled at the end of the season. To limit the number of parameters reproduction is limited to the division of the invested biomass in reproduction by the species specific seed biomass into a round number of seeds (the number of seed per plant could also be a differentiation axis). Clonal reproduction is not explicitly represented but can be mimic with bigger seeds and by adding a dispersion process around the parents. The seeds then are added to a potential seed-bank. This potential seed-bank is sampled, after eventual invasion, and merged with the existing seed-bank.

Reproduction & persistence

Control on the sampling process allows to model different type of ecosystems and test different hypothesis on invasions impact on community dynamics. The link between the community and the meta-community can also be explored through seed-bank control.

Three types of invasion/reproduction are currently implemented:

- closed environment reproduction: the seeds produced in the community return to the community, no invasion, the seed-bank size can be limited by a seed density limiting calculation explosions and simulating density mortality. Such mechanism should in theory lead to low diversity unless close equivalence between some species;
- constant reproduction in open environment: the seed-bank is generated at the meta-population levels, all species have the same biomass invested in reproductive pool independently from the local performance and seeds are randomly sampled. This mechanism stabilize greatly the system by does not allow to explore the meta-community dynamics and selection processes;
- productivity dependent reproduction in open environment: this mechanism is similar to the previous system but incorporate the productivity of the system by defining the seed input biomass as the total invested biomass in reproduction in the system at the end of the season. System is stabilize but the overall productivity impacts the seed-bank dynamic.

**Persistence** Some grasses are perennial and persist over the cold season. This is allowed in the model by investment in storage tissues instead of reproductive tissues. This mechanism allows the plant to benefit from the same conditions and to maintain below-ground biomass. At the end of the season, market by the snow cover, these plants (with non-null storage biomass) loss most of their above-ground biomass.

Explore management effect on the community is one of the aim of the *MountGrass* model. The management of mountain grassland will be explore only of the aspect of biomass removal, as productivity changes can be explore by changing the parameters value as the

Grazing/cutting

nutrients are not explicitly modelled. The management sub-model is not detailed here but it is based on the mapping of biomass and target trait (e.g. fraction of structural biomass as proxy for digestibility). Both cutting and grazing can be modelled but require management plan in the form of calendar of management operation and a cutting height or harvest objective.

### *Limitations and problems*

#### *Link to the real world and data*

The generalized framework introduced in *MountGrass* allows to create a rich community in a high number of dimension strategy space, it however comes with downsides.

One of the first problem is that some parameters (not explicitly detailed here) are hard to access (e.g. tissue density of active, or structural, tissue). It makes the calibration long as the incertitude for some parameters is very high. This is problematic when calibration is made difficult by a large execution time (see subsection below).

Another issue with such model is that the high dimensionality of the species strategy space allows a lot of different strategies that are not viable. This could be overcome by selection mechanism over multiple plots, but again require a lot of simulation. Moreover, there are dependencies between viable strategies and parameter values that makes it hard to restrict meta-community to viable species to set-up calibration runs.

It is possible to extract summary statistics from the model output and compare them to information from collected data making calibration and community analysis easy. However going from the data to feed the model is harder, indeed without a great knowledge of a species it is hard to define its representation within the model framework. To do so would require the knowledge of the plasticity capacity to set the reactivity, anatomical traits to define default ratios of active over structural tissues, and climatic niche to define the *a priori* estimation of external conditions. Without making direct association with real species, it is possible and interesting to try to reproduce some strategies and explore their response to various conditions.

#### *Technical problems*

The model is implemented in R with some limiting function using RCPP to speed up the process. Simulations are fairly slow compare to theoretical CPP equivalent code. The main problem is in the choice of the data structure. Indeed agents are stored in data.frames that are often modified with the `mutate` function, that makes the implementation much easier and the code readable, but slow down the execution due to constant condition checking on operations. This makes calibration routine methods almost impossible to use as they

demand a very number of runs to be efficient.

The slowness of the model also limit to simple algorithms for the research of favourable positions in the allocation space.
